SUMMARY. To address uncertainty of whether clinical stage groupings (cTNM) for esophageal cancer share prognostic implications with pathologic groupings after esophagectomy alone (pTNM), we report data—simple descriptions of patient characteristics, cancer categories, and non-risk-adjusted survival—for clinically staged patients from the Worldwide Esophageal Cancer Collaboration (WECC). Thirty-three institutions from six continents submitted data using variables with standard definitions: demographics, comorbidities, clinical cancer categories, and all-cause mortality from first management decision. Of 22,123 clinically staged patients, 8,156 had squamous cell carcinoma, 13,814 adenocarcinoma, 116 adenosquamous carcinoma, and 37 undifferentiated carcinoma. Patients were older (62 years) men (80%) with normal body mass index (18.5–25 kg/m², 47%), little weight loss (2.4 ± 7.8 kg), 0-1 ECOG performance status (67%), and history of smoking (67%). Cancers were cT1 (12%), cT2 (22%), cT3 (56%), cN0 (44%), cM0 (95%), and cG2-G3 (89%); most involved the distal esophagus (73%). Non-risk-adjusted survival for squamous cell carcinoma was not distinctive for early cT or cN; for adenocarcinoma, it was distinctive for early versus advanced cT and for cN0 versus cN+. Patients with early cancers had worse survival and those with advanced cancers better survival than expected from equivalent pathologic cate-
categories based on prior WECC pathologic data. Thus, clinical and pathologic categories do not share prognostic implications. This makes clinically based treatment decisions difficult and pre-treatment prognostication inaccurate. These data will be the basis for the 8th edition cancer staging manuals following risk adjustment for patient characteristics, cancer categories, and treatment characteristics and should direct 9th edition data collection.

**KEY WORDS:** cancer staging, data sharing, decision-making, prognostication, survival.

**INTRODUCTION**

Initial therapeutic decisions for patients with esophageal cancer, the goal of which is to maximize survival while minimizing cancer treatment harm, are driven largely by clinical cancer staging information. Assignment of clinical stage grouping (cTNM) has, by tradition, shared pathologic stage groupings (pTNM) corresponding to cTNM, but whether prognostic significance of pTNM is shared with cTNM is uncertain.

To address this uncertainty, a six-continent Worldwide Esophageal Cancer Collaboration (WECC) was mounted to collect patient characteristics, clinical esophageal cancer categories, and all-cause mortality to (i) test the hypothesis that clinical and pathologic categories share the same prognostic implications; (ii) facilitate pre-treatment prognostication; (iii) improve clinical decision-making; and (iv) prepare for the 8th edition of the cancer staging manuals following risk adjustment.

In this paper, we simply report the descriptive dataset of patient characteristics and cancer categories of individuals with clinically staged cancers and non-risk-adjusted survival that begin to address these aims.

**PATIENTS AND METHODS**

**Data**

In 2012, 79 institutions were invited to participate in WECC, aimed at constructing refined data-driven esophageal cancer staging for the 8th edition of the cancer staging manuals. They were invited based on known volumes, indication that they had accessible data, and location around the world. Of these, 41 institutions obtained local ethics-board approval of databases and executed data-use agreements with Cleveland Clinic. Data were requested in completely de-identified form (Health Insurance Portability and Accountability Act research standards) for analysis, using a set of required variables with standard definitions. Variables included demographics, comorbidities, cancer categories, cancer treatment, and time-related outcomes. The Case Cancer Institutional Review Board of Case Western Reserve University and the Cleveland Clinic Institutional Review Board approved the entire project. This paper reports results of clinical data from 33 institutions whose data were submitted by September 30, 2014, and were cleaned and adjudicated (Table A1 in Appendix).

**Patients**

At these institutions, of 22,654 patients (supporting information Table S1) with epithelial cancers, the majority were older men with normal body mass index, no weight loss, and 0-1 Eastern Cooperative Oncology Group (ECOG) performance status. Comorbidities were present in a minority of patients, with cardiopulmonary comorbidities predominating. Among the 22,654 patients, 22,123 had clinical staging data available before treatment. These data revealed that patients with pure adenocarcinoma were older than those with pure squamous cell carcinoma (Table 1), were far less likely to be female, were considerably larger, and were more likely to have diabetes, coronary artery disease, and hypertension; however, they were in better ECOG status and had normal FVC. Although six continents are represented, most patients in the dataset were treated in North America, Europe, and Asia. Patients with adenocarcinoma lived predominantly in the West and those with squamous cell carcinoma in the East.

**Endpoint**

The endpoint was all-cause mortality from the first management decision. Median potential follow-up, if there were no deaths, was 8.9 years (25% >13.4 years, 10% >20 years), but considering deaths in this elderly population with a rapidly lethal cancer, overall median follow-up was 1.6 years; median follow-up for surviving patients was 2.5 years, with 25% followed more than 5.1 years and 10% more than 8.4 years.

**Data analysis**

For analysis, patients with adenosquamous and undifferentiated carcinoma (supporting information Table S2) were considered in both the squamous cell carcinoma and adenocarcinoma datasets. Survival was estimated using the Kaplan–Meier method, and these estimates are accompanied by 68% confidence limits, equivalent to ±1 standard error. Survival has been simply stratified by a number of patient characteristics and cancer categories, with no risk adjustment. The hazard function for death was estimated by a parametric temporal decomposition method (for additional details, see http://www.lerner.ccf.org/qhs/software/hazard). Continuous variables are summarized by...
RESULTS

Clinical cancer categories

Histopathologic cell type was squamous cell carcinoma in 8,156, adenocarcinoma in 13,814, adenosquamous carcinoma in 116, and undifferentiated carcinoma in 37. Approximately a third of all cancers were confined to the esophageal wall (cT2 or less) for both squamous cell carcinoma and adenocarcinoma (Table 2 and supporting information Tables S3 and S4). Fewer than half the patients were free of regional lymph node metastasis (cN0), and few cancers had distant metastases (cM). The majority of cancers were G2/G3. Adenocarcinomas were located predominantly in the lower esophagus, and squamous cell carcinomas in the middle and lower esophagus. Otherwise, cancer categories differed only modestly.

Non–risk-adjusted survival

Overall survival was 98, 74, 36, and 24% at 30 days and 1, 5, and 10 years, respectively (supporting information Fig. S1). For both histopathologic cell types, risk of death peaked at 1 year, then gradually decreased and plateaued by about 5 years to a near constant rate of 8% per year (supporting information Fig. S2).

Clinical categories (cTNM).

Survival was similar for patients with cTis and cT1 cancers, but better for those with adenocarcinoma than squamous cell cancer
It decreased with increasing cT for cT2-4a cancers. Survival decreased with increasing cN for adenocarcinoma but not for squamous cell carcinoma (Fig. 2). These decreases were much more distinctive with increasing cT for squamous cell carcinoma than for adenocarcinoma when stratified by cN0 (because of the better survival of patients with cTis-cT1 adenocarcinomas) (Fig. 3) and cN+ (Fig. 4). Survival was poor in the presence of distant metastases (cM1) (Fig. 5). Generally, patients with early cancers had worse survival, and those with advanced cancers better survival, than expected from equivalent pathologic categories based on prior WECC data.

Other cancer categories. Survival decreased with increasing histologic grade for G1-4 cancers (supporting information Fig. S3); however, it was considerably better for patients with G1 adenocarcinomas than those with squamous cell carcinoma. Survival increased with a more distal location of cancer within the esophagus (supporting information Fig. S4).

Other characteristics. Survival decreased with advancing age (supporting information Fig. S5) and was worse for men with squamous cell carcinoma than for women, but similar between sexes for adenocarcinoma (supporting information Fig. S6). Survival was highly heterogeneous among institutions (supporting information Fig. S7).

### DISCUSSION

**Appropriateness of shared stage categories**

Comparing survival based on clinical cancer categories to that of equivalent pathologic categories based on esophagectomy alone for the 7th edition of the cancer staging manuals, it is evident that prognostic implications for clinical categories will not be equivalent to those of pathologic categories. The prognosis for these clinically staged early cancers was clearly worse, indicating that cTNM for these cancers was understaged compared to pTNM. This is particularly troublesome for therapeutic decisions about endoscopic therapies performed under the assumption that the cancer is early stage, without regional nodal or distant metastases. Prognosis for these early clinically staged cancers will be overly optimistic. Conversely, apparently advanced cTNM cancers carry a somewhat better prognosis.
than equivalent pTNM cancers. In part, this may be due to clinically overstaging early cancers and in part to the effect of neoadjuvant and adjuvant therapy for more advanced stage cancers. This is troublesome because it may expose patients with clinically overstaged early cancers and non-responders to unnecessary or ineffective neoadjuvant therapy.

Principal findings

Clinical staging appeared to be adequate for separating early cTis-1N0M0 cancers from more advanced cancers, with survival better and more distinctive for adenocarcinoma than squamous cell carcinoma, but discrimination among early cancers was poor. Discrimination among advanced cancers was slightly better, but of questionable practical value. These observations highlight the deficiencies of current clinical staging.

WECC and data assemblage

WECC data for the 7th edition staging manuals was based on pathologic staging of patients undergoing esophagectomy alone. This new WECC effort included collecting clinical staging data for patients undergoing all treatments. The number of patient characteristic variables was greater and the data more complete than in the prior WECC effort. Thus, this was a global effort of considerable magnitude across geography, institutions, patients, cancer categories, and treatments. These data will be the basis for the 8th edition cancer staging manuals following risk adjustment for all these variables.

Clinical patient characteristics

In this WECC experience, esophageal cancer was found to be a disease of older men, although more so for adenocarcinoma than squamous cell carcinoma. Because the majority of patients underwent treatment with curative intent, most had good to excellent performance status, and no weight loss. Comorbidities were numerous and clinically significant; collection of these data was essential for risk adjustment of all-cause mortality.

Clinical cancer categories

The majority of cancers were locally advanced, with invasion into the adventitia (cT3) and metastases to regional lymph nodes (cN+). However, except for cancers so advanced that only palliative therapy was
offered, there were a sufficient number of patients to provide a wide spectrum of clinically staged esophageal cancers.

Histologic grade 2 and 3 predominated in both cell types. There was a smaller proportion of grade 1 cancers in this dataset than in the prior WECC effort, because it includes more than esophagectomy-only patients. G4 cancers were uncommon. Location was predominately lower thoracic esophagus; few patients had adenocarcinoma of the middle thoracic esophagus and rarely of the upper thoracic esophagus. Distribution of location for squamous cell carcinoma, although skewed to the middle and lower thoracic esophagus, will be sufficient to permit analysis of the effect of location on risk-adjusted survival. No patient with cervical esophageal cancer was included in the dataset.

Non–risk-adjusted survival

The endpoint for this study was all-cause mortality. This was chosen because it is a hard endpoint not requiring interpretation. Recording multiple patient comorbidities will permit extensive risk adjustment, which provides a truer reflection of death due to cancer than the softer endpoint of disease-specific mortality.

Overall survival was similar for squamous cell carcinoma and adenocarcinoma. This surprising fact reflects important differences in patient characteristics and cancer categories between these groups. Except for cTisN0M0 and cT1N0M0 cancers, unadjusted survival was more distinctive when combining cT with cN. Survival was distinctive for histologic grades cG1-G4 and location. Regardless of histopathologic cell type, survival curves for cancer categories ‘pinched’ together compared with pathologic staging. This ‘regression toward the mean’ has many possible explanations, including (i) understaging of early clinical cancers accentuated by the ceiling of cTis; (ii) failure to use, or ineffectual use of, staging modalities such as endoscopic mucosal resection (EMR), EUS-FNA (endoscopic ultrasound-directed fine needle aspiration), and CT-PET for suspected early cancers; (iii) overstaging of advanced clinical cancers due to a floor of cT4b, cN3, and cM1; and (iv) unpredictability of effectiveness of neoadjuvant treatment (downstaging) of advanced clinical cancers, resulting in intermediate survival for some of these cancers that have poor

pretreatment prognosis. This highlights the need for risk adjustment and a type of multivariable analysis that accounts for treatment effects as well as patient and cancer categories.

**Strengths and limitations**

Currently, this is the best attempt at providing worldwide clinical esophageal cancer staging data. However, clinical staging was not uniform among centers or across continents, and these heterogeneities generated heterogeneous survival. Patients treated in North America, Europe, and Asia predominated. Unlike most registry data, WECC collected more patient characteristics, cancer categories, and specific treatments. However, values for some variables were not recorded (missing data). Patients included in the study were undoubtedly biased away from metastatic cancer and palliative treatment. Data were similarly limited for untreatable patients, such as those with T4b and M1 cancers.

The database also reflects temporal changes in treatment from esophagectomy alone to neoadjuvant therapy for advanced cancer. Nevertheless, older data on esophagectomy alone, which may seem a limitation, are crucial for developing pathologic staging of advanced esophageal cancers.

A limitation of this pure data presentation is that it does not account for patient variables that affect all-cause mortality; the interplay among TNM, histopathologic cell type, histologic grade, and cancer location in part due to the unique lymphatic anatomy of the esophagus; and the confounding of treatment effects, temporal factors, etiology, diagnosis, and clinical decision-making around the world.

**Clinical staging implications**

Today, esophagogastroduodenoscopy (EGD) and biopsy are necessary for determining location, histopathologic cell type, and histologic grade; EMR and EUS for cT; EUS-FNA for cN; and CT-PET for cM and cN; supplemented by ancillary imaging, aspiration, or biopsy.

Comprehensive clinical staging as described is problematic because of varying cost limitations and regional availability of staging modalities. Minimal worldwide standards for clinical staging must be set with worldwide adherence expected. Recording how clinical stage was obtained is necessary to determine quality of clinical staging. There is a need for more accurate and precise clinical staging modalities. Addition of other patient characteristics and cancer categories will permit better treatment decisions and more accurate pre-treatment prognostication.

**CONCLUSIONS**

Comparing these clinical data with WECC pathologic data for the 7th edition cancer staging manuals, it became evident that clinical categories did not share the same prognostic implications as pathologic categories after esophagectomy alone. The pinching of survival data makes pre-treatment prognostication difficult, providing overly optimistic prognostication for patients with early-stage cancers and overly pessimistic prognostication for those with advanced clinical stage cancers. This makes clinical decision-making difficult.

These clinical staging data will be the basis for the 8th edition cancer staging manuals following risk adjustment for many confounding variables. These findings should direct data collection for the 9th edition. This is a milestone in the clinical staging of esophageal cancer and provides direction for future advancements.
